Abstract

The number of triangulations of a planar n point set is known to be c^n , where the base c lies between 2.43 and 30. The fastest known algorithm for counting triangulations of a planar n point set runs in $O^*(2^n)$ time. The fastest known arbitrarily close approximation algorithm for the base of the number of triangulations of a planar n point set runs in time subexponential in n . We present the first quasi-polynomial approximation scheme for the base of the number of triangulations of a planar point set.

1 Introduction

A *triangulation* T of a set S of n points in the Euclidean plane is a maximal set of properly non-intersecting straight-line segments with both endpoints in S . These straight-line segments are called *edges* of T . Let $F(S)$ stand for the set of all triangulations of S .

The problem of computing the number of triangulations of S , i.e., $|F(S)|$, is easy when S is convex. Simply, by a straightforward recurrence, $|F(S)| = C_{n-2}$, where C_k is the k -th Catalan number, in this special case. However, in the general case, the problem of computing the number of triangulations of S is neither known to be $\#P$ -hard nor known to admit a polynomial-time counting algorithm.

It is known that $|F(S)|$ lies between $\Omega(2.43^n)$ [9] and $O(30^n)$ [8]. Since the so called flip graph whose nodes are triangulations of S is connected [7], all

†Research supported in part by VR grant 621-2011-6179.

triangulations of S can be listed in exponential time by a standard traversal of this graph. Only recently, Alvarez and Seidel have presented an elegant algorithm for the number of triangulations of S running in $O^*(2^n)$ time [4] which is substantially below the aforementioned lower bound on $|F(S)|$ (the O^* notation suppresses polynomial in n factors).

Also recently, Alvarez, Bringmann, Ray, and Seidel [3] have presented an approximation algorithm for the number of triangulations of S based on a recursive application of the planar simple cycle separator [6]. Their algorithm runs in subexponential $2^{O(\sqrt{n} \log n)}$ time and over-counts the number of triangulations by at most a subexponential $2^{O(n^{\frac{3}{4}} \sqrt{\log n})}$ factor. It also yields a subexponential-time approximation scheme for the base of the number of triangulations of S , i.e., for $|F(S)|^{\frac{1}{n}}$. The authors of [3] observe also that just the inequalities $\Omega(2.43^n) \leq |F(S)| \leq O(30^n)$ yield the large exponential approximation factor $O(\sqrt{30/2.43}^n)$ for $|F(S)|$ trivially computable in polynomial time.

1.1 Our contribution

We take a similar approximation approach to the problem of counting triangulations of S as Alvarez, Bringmann, Ray, and Seidel in [3]. However, importantly, instead of using recursively the planar simple cycle separator [6], we apply recursively the so called balanced α -cheap l -cuts of maximum independent sets of triangles within a dynamic programming framework developed by Adamaszek and Wiese in [1, 2]. By using the aforementioned techniques, the authors of [1] designed the first quasi-polynomial time approximation scheme (QPTAS) for the maximum weight independent set of polygons belonging to the input set of polygons with poly-logarithmically many edges.

Observe that a triangulation of S can be viewed as a maximum independent set of triangles drawn from the set of all triangles with vertices in S that are free from other points in S (triangles, or in general polygons, are identified with their open interiors). This simple observation enables us to use the aforementioned balanced α -cheap l -cuts recursively in order to bound an approximation factor of our approximation algorithm. The parameter α specifies the maximum fraction of an independent set of triangles that can be destroyed by the l -cut, which is a polygon with at most l vertices in a specially constructed set of points of polynomial size.

Similarly as the approximation algorithm from [3], our algorithm may over-count the true number of triangulations because the same triangulation can be partitioned recursively in many different ways. In contrast with the approximation algorithm in [3], our algorithm may also under-count the number of triangulations of S , since our partitions generally destroy a fraction of triangles in a complete triangulation of S .

Our approximation algorithm for the number of triangulations of a set S of n points with integer coordinates in the plane runs in $n^{(\log(n)/\epsilon)^{O(1)}}$ time. For $\epsilon > 0$, it returns a number at most $2^{\epsilon n}$ times smaller and at most $2^{\epsilon n}$ times larger than the number of triangulations of S . Note that even for $\epsilon = (\log n)^{-O(1)}$, the running time is still quasi-polynomial.

As a corollary, we obtain a quasi-polynomial approximation scheme for the base of the number of triangulations of S , i.e., for $|F(S)|^{\frac{1}{n}}$. This implies that the problem of approximating $|F(S)|^{\frac{1}{n}}$ cannot be APX-hard (under standard

complexity theoretical assumptions).

1.2 Organization of the paper

In Preliminaries, we introduce basic concepts of the dynamic programming framework from [2]. Section 3 presents our approximation counting algorithm for the number of triangulations of S . In Section 4, the time complexity of the algorithm is examined while in Sections 5, upper bounds on the under-counting and the over-counting of the algorithm are derived, respectively. In Section 6, our main results are formulated. We conclude with a short discussion on possible extensions of our results in Section 7.

2 Preliminaries

The Maximum Weight Independent Set of Polygons Problem (MWISP) is defined as follows [1]. We are given a set Q of n polygons in the Euclidean plane. Each polygon has at most k vertices, each of the vertices has integer coordinates. Next, each polygon P in Q is considered as an open set, i.e., it is identified with the set of points forming its interior. Also, each polygon $P \in Q$ has weight $w(P) > 0$ associated with it. The task is to find a maximum weight independent set of polygons in Q , i.e., a maximum weight set $Q' \subseteq Q$ such that for all pairs P_i, P_j of polygons in Q' , if $P_i \neq P_j$ then it holds $P_i \cap P_j = \emptyset$.

The *bounding box* of Q is the smallest axis aligned rectangle containing all polygons in Q .

Note that in particular if Q consists of all triangles with vertices in a finite planar point set S such that no other point in S lies inside them or on their perimeter, each having weight 1, then the set of all maximum independent sets of polygons in Q is just the set of all triangulations of S . We shall denote the latter set by $F(S)$.

Adamaszek and Wiese have shown that if $k = \text{poly}(\log n)$ then MWISP admits a QPTAS [1].

Fact 1 ([1]). *Let k be a positive integer. There exists a $(1 + \epsilon)$ -approximation algorithm with a running time of $(nk)^{(\frac{k}{\epsilon} \log n)^{O(1)}}$ for the Maximum Weight Independent Set of Polygons Problem provided that each polygon has at most k vertices.*

Recently, Har-Peled generalized Fact 1 to include arbitrary polygons [5].

We need the following tool from [1].

Definition 1. *Let $l \in \mathbb{N}$ and $\alpha \in \mathbb{R}$ where $0 < \alpha < 1$. Let T be a set of pairwise non-touching triangles. A polygon Γ is a balanced α -cheap l -cut of T if*

- Γ has at most l edges,
- the total weight of all triangles in T that intersect Γ does not exceed an α fraction of the total weight of triangles in T ,
- the total weight of the triangles in T contained in Γ does not exceed two thirds of the total weight of triangles in T ,

- the total weight of the triangles in T outside Γ does not exceed two thirds of the total weight of triangles in T .

For a set of triangles T in the plane, the set of *DP-points* consists of *basic DP-points* and *additional DP-points*. The set of basic DP-points contains the four vertices of the bounding box of T and each intersection of a vertical line passing through a corner of a triangle in T with any edge of a triangle in T or a horizontal edge of the bounding box. The set of additional DP-points consists of all intersections of pairs of straight-line segments whose endpoints are basic DP-points. The authors of [1] observe that the total number of DP-points is $O(n^4)$.

Fact 2 ([1]). *Let $\delta > 0$ and let T be a set of pairwise non-touching triangles in the plane such that the weight of no triangle in T exceeds one third of the weight of T . Then there exists a balanced $O(\delta)$ -cheap $(\frac{1}{\delta})^{O(1)}$ -cut with vertices at basic DP-points.*

By a maximal triangulation of input points within a DP-cell, we shall mean a partial triangulations of these points that cannot be extended by any edge within the cell. Next, by a maximal fragment of a triangulation R of input points, within a DP cell, we shall mean the partial triangulation consisting of all edges of R that are contained in the cell.

3 Dynamic programming

The QPTAS of Adamaszek and Wiese for maximum weight independent set of polygons [1] is based on dynamic programming. For each polygon with at most k vertices at the DP points induced by the input polygons, termed a DP cell, an approximate maximum weight independent subset of the input polygons contained in the DP cell is computed. The computation is done by considering all possible partitions of the DP cell into at most k smaller DP cells. For each such partition, the union of the approximate solutions for the component DP cells is computed. Then, a maximum weight union is picked as the approximate solution for the DP cell.

Our dynamic programming algorithm, termed Algorithm 1 and depicted in Fig. 1., is in part similar to that of Adamaszek and Wiese [1]. The set of input polygons consists of all triangles with three vertices in the input planar point set S that do not contain any other point in S . For each DP cell, an approximate number of triangulations within the cell is computed instead of an approximate maximum number of non-touching triangles within the cell. Further modification of the dynamic programming of Adamaszek and Wiese are as follows.

1. Solely those partitions of a DP cell into at most k component DP cells are considered where no component cell contains more than two thirds of the input points (i.e., the vertices of the input triangles) in the partitioned cell. (Alternatively, one could generalize the concept of a DP cell to a set of polygons with holes and consider only partitions into two DP cells obeying this restriction.)

Input: A set S of n points with integer coordinates in the Euclidean plane and natural number parameters k and Δ .

Output: An approximate number of triangulations of S .

- 1: $T \leftarrow$ the set of all triangles with vertices in S that do not contain any other point in S ;
- 2: $P \leftarrow$ a list of polygons (possibly with holes) with at most k vertices in total at DP points induced by T , topologically sorted with respect to geometric containment;
- 3: **for** each polygon $Q \in P$ containing at most Δ points in S **do**
- 4: $tr(Q) \leftarrow$ exact number of maximal triangulations of points in $S \cap Q$ within Q ;
- 5: **end for**
- 6: **for** each polygon set $Q \in P$ containing more than Δ points in S **do**
- 7: $tr(Q) \leftarrow 0$;
- 8: **for** each partition of Q into polygons $Q_1, \dots, Q_l \in P$, where $l \leq k$, no Q_j contains more than two thirds of points in $S \cap Q$, and $tr(Q_1)$ through $tr(Q_l)$ are defined **do**
- 9: $tr(Q) \leftarrow tr(Q) + \prod_{j=1}^l tr(Q_j)$;
- 10: **end for**
- 11: **end for**
- 12: Output $tr(B)$, where B is the bounding box of T .

Figure 1: Algorithm 1 for approximately counting triangulations of a finite planar point set.

2. While a partition of a DP cell into at most k cells is processed, instead of the union of the solutions to the subproblems for these cells, the product of the numerical solutions for the component DP cells is computed.
3. Instead of taking the maximum of the solutions induced by the partition of a DP cell into at most k DP-cells, the sum of the numerical solutions induced by these partitions is computed.
4. When the number of points contained in a DP cell does not exceed the threshold number Δ then the exact number of maximal triangulations within the cell is computed.

Algorithm 1 also in part resembles the approximation counting algorithm for the number of triangulations of a planar point set due to Alvarez, Bringmann, Ray, and Seidel [3]. The main difference is in the used implicit recursive partition tool. Algorithm 1 uses balanced α -cheap l -cuts within the dynamic programming framework from [2] instead of the simple cycle planar separator theorem [3, 6]. Thus, Algorithm 1 recursively partitions a DP cell defining a subproblem into at most k smaller DP-cells while the algorithm in [3] recursively splits a subproblem by a simple cycle that yields a balanced partition. The new partition tool gives a better running time since the number of possible partitions is much smaller so the dynamic programming/recursion has lower complexity and the threshold for the base case can be much lower. Since the algorithm in [3] in particular lists all simple cycles on $O(\sqrt{n})$ vertices, it runs in at least $2^{O(\sqrt{n} \log n)}$ time independently of the precision of the approximation.

4 Time complexity

The cardinality of T does not exceed n^3 . Then, by the analogy with the dynamic programming algorithm of Adamaszek and Wiese for nearly maximum independent set of triangles, the number of DP cells is $(3n^3)^{O(k)} = n^{O(k)}$ (see Proposition 2.1 in [1]). Consequently, the number of possible partitions of a DP cell into at most k DP cells is $O\left(\binom{n^{O(k)}}{k}\right)$ which is $n^{O(k^2)}$.

It follows that if we neglect the cost of computing the exact number of triangulations contained within a DP cell including at most Δ input points, then Algorithm 1 runs in $n^{O(k^2)}$ time.

We can compute the exact number of maximal triangulations contained within a DP cell with at most Δ input points by listing all complete triangulations of these points and counting only their maximal fragments within the cell that are maximal triangulations within the cell. To list the complete triangulations of the input points within a DP cell we can apply any traversal algorithm, like BFS or DFS, to the so called *flip* graph of the triangulations which is known to be connected [7]. Hence, the listing takes time proportional to the number of the triangulations, which is at most 30^Δ by [8]. It follows that extracting the maximal fragments and counting those being maximal triangulations can be done also in $2^{O(\Delta)}n^{O(1)}$ time.

We conclude with the following lemma.

Lemma 1. *Algorithm 1 runs in $n^{O(k^2)}2^{O(\Delta)}$ time.*

5 Approximation factor

5.1 Under-counting

The potential under-counting stems from the fact that when a DP cell is partitioned into at most k smaller DP cells then the possible combinations of triangulation edges crossing the partitioning edges are not counted. Furthermore, in the leaf DP cells, i.e., those including at most Δ points from S , we count only maximal triangulations while the restriction of a triangulation of S to a DP cell does not have to be maximal. See Fig. 2.

Intuitively, the general idea of the proof of our upper bound on under-counting is as follows. For each triangulation $W \in F(S)$, there is triangulation counted by Algorithm 1 that can be obtained by removal $O(\epsilon n)$ edges and augmenting with $O(\epsilon n)$ other edges. Such a triangulation is a union of maximal triangulations contained in leaf DP cells.

Lemma 2. *Let S be a set of n points in the plane and let $\epsilon > 0$. For each $W \in F(S)$, there is a partial triangulation $W^* \subseteq W$ of S containing at least a $1 - O(\epsilon)$ fraction of the triangular faces of W and a partial triangulation $M(W^*)$ of S which is an extension of W^* by $O(\epsilon n)$ edges such that the estimation returned by Algorithm 1 with k set to $\log^{O(1)}(n)/\epsilon^{O(1)}$ is not less than $|\bigcup_{W \in F(S)} \{M(W^*)\}|$.*

Proof. Let $W \in F(S)$. By adapting the idea of the proof of the approximation ratio of the QPTAS in [1], consider the following tree U of DP cells obtained by recursive applications of balanced α -cheap l -cuts.

At the root of U , there is the bounding box. By Fact 2, there is a balanced α -cheap l -cut, where $l = \alpha^{-O(1)}$, that splits the box into at most k children DP

Figure 2: An example of a maximal triangulation within a DP cell and a partition of the DP cell into smaller DP cells Q_1, \dots, Q_5 crossing some triangles in the triangulation.

cells such that only α fraction of the triangular faces of W is crossed by the cut. The construction of U proceeds recursively in children DP cells and stops in DP cells that contain at most Δ points.

Note that the height of U is not greater than $\log_{3/2} n$.

For a node u of U , let W_u be the partial triangulation of the points in the DP cell Q_u associated with u that is a restriction of W to (the vertices and edges of W contained in) Q_u . Next, let W_u^* denote the restriction of W_u to the union of W_t over the leaves t of the subtree of U rooted at u .

By induction on the height $h(u)$ of u in U , we obtain that the partial triangulation $W_u^* \subseteq W_u$ contains $(1 - \alpha)^{h(u)}$ fraction of triangular faces of W_u . Set α to $\frac{O(\epsilon)}{\log(n/\epsilon)}$. It follows in particular that for the root r of U , $W_r^* \subseteq W$ contains at least an $(1 - \alpha)^{\log_{3/2} n/\epsilon} \geq 1 - O(\epsilon)$ fraction of triangular faces in W . Set W^* to W_r^* .

For a leaf t of U , let $M(W_t)$ be an extension of W_t to a maximal triangulation within the leaf cell D_t . For a node u of U , let $M(W_u^*)$ be a partial triangulation within Q_u that is the union of $M(W_t)$ over the leaves t of the subtree of U rooted at u . We have also $M(W^*) = M(W_r^*)$ by $W^* = W_r^*$.

By the definition of $M(W^*)$, $M(W^*)$ is an extension of W^* . By the definition of W^* , any edge of $M(W^*)$ that is not an edge of W^* has both endpoints at vertices of triangles in W that are missing in W^* . It follows that the number of edges in $M(W^*) \setminus W^*$ is at most $3 \times O(\epsilon n) = O(\epsilon n)$.

We shall show by induction on $h(u)$ that Algorithm 1 while computing an estimation for Q_u at least counts the number of $M(W_u^*)$.

If $h(u) = 0$, i.e., u is a leaf in U then $W_u^* = W_u$ and consequently in particular $M(W_u^*) = M(W_u)$ is counted by Algorithm 1.

Suppose in turn that u is an internal node in U with l children u_1, \dots, u_l .

When the estimation for Q_u is computed by Algorithm 1, the sum of products of estimations yielded by different partitions of Q_u into at most k DP cells is computed. In particular, the partition into Q_{u_1}, \dots, Q_{u_l} is considered. By the induction hypothesis, the estimation for Q_{u_j} includes $M(W_{u_j}^*)$ for $j = 1, \dots, l$. Hence, the product of these estimations counts also $M(W_u^*) = \bigcup_{j=1}^l M(W_{u_j}^*)$.

By $M(W^*) = M(W_r^*)$, to obtain the lemma it remains to show that the bound $\log^{O(1)}(n/\epsilon)/\epsilon^{O(1)}$ on k is sufficiently large. Following the proof of Lemma 2.1 in [1], observe that each DP cell Q_u at each level of U is an intersection of at most $O(\log(n/\epsilon))$ polygons, each with at most l edges and vertices at basic DP points. Hence, by $\alpha = \frac{O(\epsilon)}{\log(n/\epsilon)}$ and $l = \alpha^{-O(1)}$, the resulting polygons have at most $O(l^2 \log^2(n/\epsilon)) = \log^{O(1)}(n/\epsilon)/\epsilon^{O(1)}$ edges and vertices at basic and additional DP points. \square

Theorem 1. *The under-counting factor of Algorithm 1 with k set to $\log^{O(1)}(n/\epsilon)/\epsilon^{O(1)}$ is at most $2^{O(\epsilon n \log n)}$.*

Proof. Consider any triangulation $W \in F(S)$. By Lemma 2, the partial triangulation $W^* \subseteq W$ contains at least an $1 - O(\epsilon)$ fraction of the triangular faces of W . Hence, the edges completing W^* to any triangulation in $F(S)$ can be incident only to the vertices of the triangular faces in W that do not occur in W^* . The number of the latter is at most $3 \times O(\epsilon n) = O(\epsilon n)$. It follows that the number of ways of completing W^* to a full triangulation in $F(S)$ is not greater than the number of full triangulations on $O(\epsilon n)$ vertices which is not greater than $30^{O(\epsilon n)} = 2^{O(\epsilon n)}$.

By Lemma 2, the estimation returned by Algorithm 1 with k set to $\log^{O(1)}(n/\epsilon)/\epsilon^{O(1)}$ is not less than $|\bigcup_{W \in F(S)} \{M(W^*)\}|$.

Now it remains to show that the maximum number of partial triangulations $(W')^*$, $W' \in F(S)$, for which $M((W')^*) = M(W^*)$ is at most $2^{O(\epsilon n \log n)}$. To see this observe that the edges extending $(W')^*$ to $M((W')^*)$ are incident to at most $O(\epsilon n)$ vertices of the $O(\epsilon n)$ triangular faces of W' that are missing in $(W')^*$. Consequently, the maximum number of such partial triangulations $(W')^*$ is upper bounded by the number of subsets of at most $O(\epsilon n)$ edges of $M(W^*)$ (whose removal may form a partial triangulation $(W')^*$ satisfying $M((W')^*) = M(W^*)$). The latter number is $2^{O(\epsilon n \log n)}$.

We conclude that for $W \in F(S)$, the number of other triangulations $W' \in F(S)$ for which $M((W')^*) = M(W^*)$ is at most $2^{O(\epsilon n)} 2^{O(\epsilon n \log n)} = 2^{O(\epsilon n \log n)}$. Now, the theorem follows from Lemma 2. \square

5.2 Over-counting

The reason for over-counting in the estimation returned by our algorithm is as follows. The same triangulation within a DP cell may be cut in the number of ways proportional to the number of considered partitions of the DP cell into at most k smaller DP-cells. This reason is similar to that for over-counting of the approximation triangulation counting algorithm of Alvarez, Bringmann, Ray, and Seidel [3] based on the planar simple cycle separator theorem. Therefore, our initial recurrences and calculations are similar to those derived in the analysis of the over-counting from [3].

Lemma 3. *Let Q be an arbitrary DP cell processed by Algorithm 1 which contains more than Δ input points. Recall the calculation of the estimation for Q by summing the products of estimations for smaller DP cells Q_1, \dots, Q_l over $n^{O(k^2)}$ partitions of Q into Q_1, \dots, Q_l , $l \leq k$. Substitute the true value of the number of maximal triangulations within each such smaller cell Q_i for the estimated one in the calculation. Let r be the resulting value. The number of maximal triangulations within Q is at least $r/n^{O(k^2)}$.*

Proof. Note that r is the sum of the number of different combinations of maximal triangulations within smaller DP cells Q_1, \dots, Q_l over $n^{O(k^2)}$ partitions of Q into smaller cells Q_1, \dots, Q_l , $l \leq k$. Importantly, each such combination can be completed to some maximal triangulation within Q but no two different combinations coming from the same partition Q_1, \dots, Q_l can be extended to the same maximal triangulation within Q .

Let M be the set of maximal triangulations W within Q for which there is a partition into smaller DP cells Q_1, \dots, Q_l , $l \leq k$, such that for $i = 1, \dots, l$, W constrained to Q_i is a maximal triangulation within Q_i . Note that for each $W \in M$, the number of the combinations that can be completed to W cannot exceed that of the considered partitions, i.e., $n^{O(k^2)}$, as each of the combinations has to come from a distinct partition Q_1, \dots, Q_l .

Thus, there is a binary relationship between maximal triangulations within Q that belong to M and the aforementioned combinations. It is defined on all the maximal triangulations in M and on all the combinations, and a maximal triangulation in M is in relation with at most $n^{O(k^2)}$ combinations. This yields the lemma. \square

By Lemma 3, we can express the over-counting factor $L(Q, \Delta)$ of Algorithm 1 for a DP cell Q by the following recurrence:

$$L(Q, \Delta) = \sum_{(Q_1, \dots, Q_l)} \prod_{j=1}^l L(Q_j, \Delta) \leq n^{O(k^2)} \prod_{j=1}^{l^*} L(Q_j^*, \Delta)$$

where the summation is over all partitions of Q into DP cells Q_1, \dots, Q_l , where $l \leq k$, and $Q_1^*, \dots, Q_{l^*}^*$ is a partition that maximizes the term $\prod_{j=1}^l L(Q_j, \Delta)$. When Q contains at most Δ input points, Algorithm 1 computes the exact number of maximal triangulations of these points within Q . Thus, we have $L(Q, \Delta) = 1$ in this case.

Following [3], it will be more convenient to transform our recurrence by taking logarithm of both sides. For any DP cell P , let $L'(P, \Delta) = \log L(P, \Delta)$. We obtain now:

$$L'(Q, \Delta) \leq O(k^2 \log n) + \sum_{j=1}^{l^*} L'(Q_j^*, \Delta)$$

Lemma 4. *Let B be a bounding box for a set S of n points in the plane. The following equality holds*

$$L'(B, \Delta) = O(k^2 n \log^2 n / \Delta)$$

Proof. Let U be the recurrence tree and let D be the set of direct ancestors of leaves in U . For each node $d \in D$, the corresponding DP cell includes at least

$\Delta + 1$ points in S . It follows that $|D| \leq n/\Delta$. Also, any node in D has depth $O(\log n)$ in U . Consequently, the contribution of the subproblems corresponding to nodes in D and their ancestors to the estimation for $L'(B, \Delta)$ can be upper bounded by $O(k^2 \log n \times (n/\Delta) \log n)$. Finally, recall that the subproblems corresponding to leaves of U do not contribute to the estimation. \square

Lemma 3 immediately yields the following corollary.

Theorem 2. *Let B be a bounding box for a set of n points in the plane. Set the parameter k in Algorithm 1 as in Theorem 1. If for $\epsilon > 0$ the parameter Δ in Algorithm 1 is set to $\frac{\epsilon}{c} k^2 \log^2 n$ for sufficiently large constant c then the over-counting factor is at most $2^{\epsilon n}$.*

6 Main result

By combining Lemma 1 with Theorems 1, 2 with ϵ set to $\epsilon/\log n$, we obtain our main result.

Theorem 3. *There exists an approximation algorithm for the number of triangulations of a set S of n points with integer coordinates in the plane with a running time of at most $n^{(\log(n)/\epsilon)^{O(1)}}$ that returns a number at most $2^{\epsilon n}$ times smaller and at most $2^{\epsilon n}$ times larger than the number of triangulations of S .*

Corollary 1. *There exists a $(1 + \epsilon)$ -approximation algorithm with a running time of at most $n^{(\log(n)/\epsilon)^{O(1)}}$ for the base of the number of triangulations of a set of n points with integer coordinates in the plane.*

Proof. Let c^n be the number of triangulations of the input n point set, and let Λ be the number returned by the algorithm from Theorem 3. We have $\max\{\frac{c^n}{\Lambda}, \frac{\Lambda}{c^n}\} \leq 2^{\epsilon n}$ by Theorem 3. By taking the n -th root on both sides, we obtain $\max\{\frac{c}{\Lambda^{1/n}}, \frac{\Lambda^{1/n}}{c}\} \leq 2^\epsilon$. Now it is sufficient to observe that $2^\epsilon < 1 + \epsilon$ for $\epsilon < \frac{1}{2}$. \square

7 Extensions

Adamaszek and Wiese presented also an extension of their theorem on α -cheap cut of an independent set of triangles (Fact 2) to include independent polygons with at most K edges (Lemma 3.1 [1]). This makes possible to generalize our QPTAS to include the approximation of the number of maximum weight partitions into K -gons.

Acknowledgments

We thank Victor Alvarez, Artur Czumaj, Peter Floderus, Mirosław Kowaluk, Christos Levcopoulos and Mia Persson for preliminary discussions on counting the number of triangulations of a planar point set. We are also very grateful to unknown referees for pointing out an imprecision in the under-counting analysis in a preliminary version of our paper as well as and many other valuable comments.
